Blood neurofilament light chain as a biomarker of MS disease activity and treatment response

Jens Kuhle, MD,* Harald Kropshofer, PhD,* Dieter A. Haering, PhD, Uma Kundu, MPharm, Rolf Meinert, PhD, Christian Barro, MD, Frank Dahlke, MD, Davorka Tomic, PhD, David Leppert, MD, and Ludwig Kappos, MD

Published February 8, 2019

Conclusions:

Blood NfL levels are associated with clinical and MRI-related measures of disease activity and neuroaxonal damage and have prognostic value. Our results support the utility of blood NfL as an easily accessible biomarker of disease evolution and treatment response.

Long-term Effect of Fingolimod in Reducing Blood Neurofilament Light Levels in Patients with Relapsing-remitting Multiple Sclerosis

Jeffrey Cohen[1], Ludwig Kappos[2], Nadia Tenenbaum[3], Jackie Han[3], Harald Kropshofer[4], Davorka Tomic[4], Jens Kuhle[2]
[1]Cleveland Clinic, [2]Neurologic Clinic and Policlinic, Department of Medicine, Clinical Research, Biomedicine and Biomedical Engineering, University Hospital and University of Basel, [3]Novartis Pharmaceuticals Corporation, [4]Novartis Pharma AG

Objective:
To assess the effect of long-term treatment with fingolimod on blood neurofilament light chain (NfL) levels in patients with relapsing-remitting multiple sclerosis (RRMS).
Background:
NfL, a cytoskeleton protein, is elevated in blood upon neuroaxonal damage. Blood NfL is a promising biomarker for monitoring disease activity, treatment response, and prognosis in MS.
Design/Methods:
This post hoc analysis was based on data from patients who received fingolimod 0.5 mg once daily or placebo/interferon ß-1a (IFN) 30 µg once weekly in pivotal studies (24-month FREEDOMS/12-month TRANSFORMS), and then fingolimod in the open-label LONGTERMS extension study for up to 10 years. The analysis included a subset of patients who had blood NfL assessments at baseline, end of core (EoC) in pivotal studies, and end of study (EoS) in LONGTERMS. Patients were categorized into two groups: a continuous group (n=37) who received fingolimod throughout the studies and a switched group (n=42) who transitioned from placebo/IFN group to fingolimod in the LONGTERMS. NfL was measured using Single Molecule Array (Simoa™) immunoassay. The geometric mean change in NfL levels from baseline to EoS was analyzed using Wilcoxon signed-rank test.
Results:
The mean exposure to fingolimod was 3483 days in the continuous group and 2822 days in the switched group. In the continuous group, baseline NfL levels of 33 pg/mL were significantly reduced by approximately 40% at both EoC and EoS (20 pg/mL; P<0.0001 and P<0.0002, respectively). In the switched group, baseline NfL levels of 29 pg/mL were reduced by 15% at EoC (25 pg/mL, P=0.44) and 41% at EoS (17 pg/mL, P<0.0001).
Conclusions: Fingolimod 0.5 mg significantly reduced blood NfL, maintaining its low levels with continuous treatment for up to 10 years. NfL levels were reduced to a lesser extent during treatment with IFN but decreased further with switch to fingolimod, demonstrating the greater impact of highly effective therapy in RRMS.

RESEARCH ARTICLE

Serum Neurofilament Light: A Biomarker of Neuronal Damage in Multiple Sclerosis

Giulio Disanto, MD, PhD,[1] Christian Barro, MD,[2] Pascal Benkert, PhD,[3] Yvonne Naegelin, MD,[2] Sabine Schädelin, MSc,[3] Antonella Giardiello, MD,[1] Chiara Zecca, MD,[1] Kaj Blennow, PhD,[4] Henrik Zetterberg, PhD,[4,5] David Leppert, MD,[2] Ludwig Kappos, MD,[2] Claudio Gobbi, MD,[1] Jens Kuhle, MD, PhD,[2] and the Swiss Multiple Sclerosis Cohort Study Group

Objective: Neurofilament light chains (NfL) are unique to neuronal cells, are shed to the cerebrospinal fluid (CSF), and are detectable at low concentrations in peripheral blood. Various diseases causing neuronal damage have resulted in elevated CSF concentrations. We explored the value of an ultrasensitive single-molecule array (Simoa) serum NfL (sNfL) assay in multiple sclerosis (MS).

Methods: sNfL levels were measured in healthy controls (HC, $n = 254$) and two independent MS cohorts: (1) cross-sectional with paired serum and CSF samples ($n = 142$), and (2) longitudinal with repeated serum sampling ($n = 246$, median follow-up = 3.1 years, interquartile range [IQR] = 2.0–4.0). We assessed their relation to concurrent clinical, imaging, and treatment parameters and to future clinical outcomes.

Results: sNfL levels were higher in both MS cohorts than in HC ($p < 0.001$). We found a strong association between CSF NfL and sNfL ($\beta = 0.589$, $p < 0.001$). Patients with either brain or spinal (43.4pg/ml, IQR = 25.2–65.3) or both brain and spinal gadolinium-enhancing lesions (62.5pg/ml, IQR = 42.7–71.4) had higher sNfL than those without (29.6pg/ml, IQR = 20.9–41.8; $\beta = 1.461$, $p = 0.005$ and $\beta = 1.902$, $p = 0.002$, respectively). sNfL was independently associated with Expanded Disability Status Scale (EDSS) assessments ($\beta = 1.105$, $p < 0.001$) and presence of relapses ($\beta = 1.430$, $p < 0.001$). sNfL levels were lower under disease-modifying treatment ($\beta = 0.818$, $p = 0.003$). Patients with sNfL levels above the 80th, 90th, 95th, 97.5th, and 99th HC-based percentiles had higher risk of relapses (97.5th percentile: incidence rate ratio = 1.94, 95% confidence interval [CI] = 1.21–3.10, $p = 0.006$) and EDSS worsening (97.5th percentile: OR = 2.41, 95% CI = 1.07–5.42, $p = 0.034$).

Interpretation: These results support the value of sNfL as a sensitive and clinically meaningful blood biomarker to monitor tissue damage and the effects of therapies in MS.

Blood test could detect Alzheimer's up to 16 years before symptoms begin, study says

UFC's Allen Crowder Has 'No Hard Feelings' Toward Greg Hardy...

(CNN) — A simple blood test could predict if a patient will develop Alzheimer's disease up to 16 years before symptoms begin, a new study finds.

By measuring changes in the levels of a protein in the blood, called neurofilament light chain (NfL), researchers believe any rise in levels of the protein could be an early sign of the disease, according to the study published Monday in the journal Nature Medicine.

NfL is a "marker in the blood which gives an indication of nerve cell loss in the brain," explained lead researcher Mathias Jucker, professor of cell biology of neurological diseases at the German Center for Neurodegenerative Diseases. "The more neurofilament you have in the blood, the more brain damage you have," he said.

Serum neurofilament dynamics predicts neurodegeneration and clinical progression in presymptomatic Alzheimer's disease

Oliver Preische[1,2,21], Stephanie A. Schultz[3,21], Anja Apel[1,2,21], Jens Kuhle[4], Stephan A. Kaeser[1,2], Christian Barro[4], Susanne Gräber[1], Elke Kuder-Buletta[1], Christian LaFougere[1], Christoph Laske[1,2], Jonathan Vöglein[5,6], Johannes Levin[5,6], Colin L. Masters[7], Ralph Martins[8,9], Peter R. Schofield[10,11], Martin N. Rossor[12], Neill R. Graff-Radford[13], Stephen Salloway[14], Bernardino Ghetti[15], John M. Ringman[16], James M. Noble[17], Jasmeer Chhatwal[18], Alison M. Goate[19], Tammie L. S. Benzinger[3], John C. Morris[3], Randall J. Bateman[3], Guoqiao Wang[3], Anne M. Fagan[3], Eric M. McDade[3], Brian A. Gordon[3], Mathias Jucker[1,2]* and Dominantly Inherited Alzheimer Network[20]

Neurofilament light chain (NfL) is a promising fluid biomarker of disease progression for various cerebral proteopathies. Here we leverage the unique characteristics of the Dominantly Inherited Alzheimer Network and ultrasensitive immunoassay technology to demonstrate that NfL levels in the cerebrospinal fluid (n = 187) and serum (n = 405) are correlated with one another and are elevated at the presymptomatic stages of familial Alzheimer's disease. Longitudinal, within-person analysis of serum NfL dynamics (n = 196) confirmed this elevation and further revealed that the rate of change of serum NfL could discriminate mutation carriers from non-mutation carriers almost a decade earlier than cross-sectional absolute NfL levels (that is, 16.2 versus 6.8 years before the estimated symptom onset). Serum NfL rate of change peaked in participants converting from the presymptomatic to the symptomatic stage and was associated with cortical thinning assessed by magnetic resonance imaging, but less so with amyloid-β deposition or glucose metabolism (assessed by positron emission tomography). Serum NfL was predictive for both the rate of cortical thinning and cognitive changes assessed by the Mini-Mental State Examination and Logical Memory test. Thus, NfL dynamics in serum predict disease progression and brain neurodegeneration at the early presymptomatic stages of familial Alzheimer's disease, which supports its potential utility as a clinically useful biomarker.

In most neurodegenerative diseases, brain changes manifest many years before clinical symptoms become apparent. In Alzheimer's disease, presymptomatic changes in the brain include cortical thinning and neuropathological depositions containing amyloid-β and tau. These pathological changes can be assessed by magnetic resonance imaging (MRI), positron-emission tomography (PET), and measurement of amyloid-β and tau protein levels in the cerebrospinal fluid (CSF)[1–4]. However, CSF collection is invasive and imaging modalities are expensive; therefore, they are not well suited to routine clinical practice. Blood biomarkers for the presymptomatic phase of Alzheimer's disease are largely lacking, although recent progress in the analysis of amyloid-β, tau, and neurofilament light chain (NfL) in the blood have been reported[5–10].

NfL is a component of the axonal cytoskeleton and is primarily expressed in large-caliber myelinated axons[11,12]. Changes of NfL in bodily fluids have been linked to brain damage and brain atrophy in mouse models and multiple neurological disorders including

Abstract

Objective
To compare neurofilament light (NfL) and tau as blood-based biomarkers for acute sports-related concussion (SRC) and determine whether their concentrations at different time points after the injury are associated with prolonged time to return to play (RTP).

Methods
A total of 288 professional hockey players were followed longitudinally from September 1, 2012, to April 30, 2015. Data collection and biomarker analyses were conducted between 2015 and 2017. Associations were tested between blood concentrations of NfL and tau, and RTP time. Serum concentrations of S100B and neuron-specific enolase (NSE) were also measured for comparison.

Results
Of 288 players, 105 sustained an SRC. Of these, 87 underwent blood sampling 1, 12, 36, and 144 hours after SRC and at the RTP time point. Serum NfL concentrations 1, 12, 36, and 144 hours after SRC were related to prolonged RTP time, and could separate players with RTP >10 days from those with RTP ≤10 days (area under the receiver operating characteristic curve [AUROC] 0.82). Also, serum NfL 144 hours after SRC discriminated players who resigned from the game due to persistent postconcussion symptoms (PCS) from those who returned to play (AUROC 0.89). Plasma tau 1 hour after SRC was related to RTP but less strongly than NfL, while S100B and NSE showed no such associations.

Conclusion
Serum NfL outperformed tau, S100B, and NSE as a biomarker for SRC. From a clinical standpoint, serum NfL may be useful to identify individuals at risk of prolonged PCS, and may aid in biomarker-informed decisions with regard to when RTP should be considered.

Ultrasensitive LIF Assay Revealed as Promising Blood Biomarker Drug Target for Pancreatic Cancer

New study targets Achilles' heel of pancreatic cancer, with promising results

Researchers discover a potential therapeutic target for deadly cancer

Date: April 17, 2019

Source: Salk Institute

Summary: Advanced pancreatic cancer is often symptomless, leading to late diagnosis only after metastases have spread throughout the body. Now, researchers have uncovered the role of a signaling protein, called LIF, that may be the Achilles' heel of pancreatic cancer.

Simoa LIF assay is more sensitive than Luminex

		Luminex				Simoa
